(Received 24 October 2011; published 26 January 2012)

The transmission of a probe field experiencing electromagnetically induced transparency and optical switching in an atomic medium enclosed in an optical cavity is investigated. Using a semiclassical input-output theory for the interaction between an ensemble of four-level atoms and three optical cavity fields coupled to the same spatial cavity mode, we derive the steady-state transmission spectra of the probe field and discuss the dynamics of the intracavity field buildup. The analytical and numerical results are in good agreement with recent experiments with ion Coulomb crystals [M. Albert et al., Nature Photon. 5, 633 (2011)].

I. INTRODUCTION

Electromagnetically induced transparency (EIT) is a quantum interference phenomenon occurring when two electromagnetic fields resonantly excite two different transitions sharing a common state [1–4]. An intense control field addressing one of the transitions can substantially modify the linear dispersion and absorption of an atomic medium for a weak probe field resonant with the second transition. Since its first observation by Boller et al. [5], EIT has been successfully exploited, for instance, to control the propagation of light pulses through an otherwise opaque medium for light storage and retrieval [6–13] and quantum memories [14–23]. Besides providing a means for controlling the linear susceptibility of an atomic medium, EIT can also be exploited for generating strong optical nonlinearities [2–4,24,25]. For instance, in the four-level atomic configuration such as the one depicted in Fig. 1(b), the nonlinear susceptibility of the medium can be strongly enhanced at the same time as the linear susceptibility is suppressed. The large cross-Kerr effect between the probe field and a third switching field can then be used, e.g., for high-efficiency photon counting [26], all-optical switching [27–29], and nonlinear optics at low-light levels [2,3,25,30,31], nonclassical state generation [32], or the realization of strongly interacting photon gases [33,34].

When such a nonlinear EIT medium is positioned in an optical cavity one first of all benefits from the enhanced interaction of the ensemble with well-defined spatiotemporal field modes. This is of great value for enhancing the effective optical depth and for realizing high-efficiency quantum memories [35–38] or Fock-state quantum filters [39]. The EIT-induced reduction of the cavity linewidth [40] can also be used to increase the sensitivity of atomic magnetometers [8,41], enhance cavity optomechanical cooling processes [42–44], and achieve lasing sensitivity of atomic magnetometers [8,41], enhance cavity linewidth [40] can also be used to increase the...
or close to a resonance with the same spatial cavity mode, which we take to be the fundamental Gaussian TEM$_{00}$ mode for simplicity. In the experiments of Ref. [61] for instance, the probe and control fields are coupled to the same longitudinal cavity mode, resonant with the 3$d$ D$_{3/2} \rightarrow 4p^0 P_{1/2}$ transition in 40Ca$^+$, with orthogonal polarizations, while the switching field is coupled to another longitudinal cavity mode, close to resonance with the 3$d$ D$_{3/2} \rightarrow 4p^2 P_{3/2}$ transition. The interaction Hamiltonian in the rotating-wave approximation and in the rotating frame is given by

$$H_{af} = -\hbar \sum_j g_j \psi_p(r_j) \cos[k_j z_j + \psi_p(r_j)] \hat{a}_p \hat{\sigma}_j^{(i)} + \text{H.c.}$$

where the $g_j$’s are the maximal single-atom coupling strengths for the transitions considered, and the $\psi_j$’s and $\varphi_j$’s are the fields’ transverse mode functions and longitudinal mode phases, respectively [62]. Since our main goal is to discuss the effects related to the spatial transverse structure of the fields we will consider for simplicity the situation where the length, $2L$, of the ensemble is much smaller than the Rayleigh range of the cavity, as, e.g., in the experiments of Ref. [61]. We thus neglect the longitudinal variations of the phases and the waists of the light fields over the length of the ensemble. We therefore set the longitudinal mode phases to 0 and assume a Gaussian transverse structure of the fields given by $\Psi_{\alpha}(r) = \exp(-r^2/w_{\alpha}^2)$ ($\alpha = p, c, s$), where $w_{\alpha}$ is the cavity waist considered. In the following we will examine two situations:

(i) The novel case in which all three fields have the same transverse mode profile and the ensemble has a large radial extension as compared to the waists, like, e.g., in the experiments of [61]. We shall refer to this situation as the all-cavity case.

(ii) The more usual situation in which the control and switching fields have a large transverse intensity profile as compared to the extension of the ensemble. This would typically be the case if these fields were interacting with the atoms not through the cavity [56–60], or for an ensemble radially confined to a region with dimension much smaller than the waists, as could be obtained, e.g., with a string of atoms or two-component ion Coulomb crystals [63]. We shall refer to such a situation, in which the transverse mode profiles of the fields can be ignored, as the standard case.

We will in addition assume that, because of their motion, the atoms are “warm” enough such that they probe any field variation along the longitudinal standing-wave structures of the fields during the characteristic time scales of the dynamics of the fields due their interactions with the atoms. As discussed, e.g., in Refs. [64–67] and in the Appendix, one can under these conditions assume averaged longitudinal couplings $\bar{g}_\alpha = g_\alpha/\sqrt{2}$ ($\alpha = p, c, s$). Keeping only the transverse spatial dependence of the cavity modes, the Hamiltonian becomes

$$H_{af} = -\hbar \sum_j \bar{g}_j \psi_p(r_j) \hat{a}_p \hat{\sigma}_j^{(i)} + \bar{g}_c \psi_c(r_j) \hat{a}_c \hat{\sigma}_j^{(i)} + \bar{g}_s \psi_s(r_j) \hat{a}_s \hat{\sigma}_j^{(i)} + \text{H.c.}$$

(2)

For comparison the “cold” atom situation where the atoms are well localized with respect to the field standing-wave structures during the interaction is treated in the Appendix.

The atom-field dynamics of the observable mean values can be standardly derived via $\hat{\sigma} = (1/\hbar)[\hat{H} , \hat{\sigma}]$, where $\hat{\sigma}$ is the mean value of observable $\hat{\sigma}$ and the total Hamiltonian $\hat{H} = H_a + H_f + H_{af}$ is the sum of the interaction Hamiltonian (2) and of the atomic and field Hamiltonians

$$H_a = -\hbar \sum_j \Delta_p \hat{a}_p^{\dagger} \hat{a}_p + \Delta_c \hat{a}_c^{\dagger} \hat{a}_c - \Delta_s \hat{a}_s^{\dagger} \hat{a}_s + \text{H.c.},$$

$$H_f = -\hbar \Delta_p \hat{a}_p^{\dagger} \hat{a}_p - \hbar \Delta_c \hat{a}_c^{\dagger} \hat{a}_c - \hbar \Delta_s \hat{a}_s^{\dagger} \hat{a}_s,$$

where $\Delta_p = \omega_p - \omega_{31}$, $\Delta_c = \omega_c - \omega_{23}$, and $\Delta_s = \omega_s - \omega_{24}$ are the one-photon detunings, and $\Delta_p^{(2)} = \omega_p - \omega_{34}^{(2)}$ are the cavity detunings between the fields with frequency $\omega_c$ and the cavity resonance frequencies considered $\omega_{24}^{(2)}$ ($\alpha = p, c, s$). Denoting by $\gamma_{31}$, $\gamma_{32}$, and $\gamma_{42}$ the spontaneous decay rates and introducing a phenomenological decay rate $\gamma_0$ for the ground-state coherence operators $\hat{\delta}_{12}^{(i)}$ ($\gamma_0 \ll \gamma_{31}, \gamma_{32}, \gamma_{42}$), one obtains the following set of coupled differential equations:

$$\dot{\delta}_{12}^{(i)} = -\gamma_0 - i(\Delta_p - \Delta_c)\sigma_{12}^{(i)} - i \bar{g}_p \psi_p(r_j) \hat{a}_p \sigma_{32}^{(i)} + i \bar{g}_c \psi_c(r_j) \hat{a}_c \sigma_{32}^{(i)}$$

$$+ i \bar{g}_s \psi_s(r_j) \hat{a}_s \sigma_{32}^{(i)}$$

$$\dot{\delta}_{13}^{(i)} = -\gamma_0 - i(\Delta_p - \Delta_s)\sigma_{13}^{(i)} - i \bar{g}_p \psi_p(r_j) \hat{a}_p \sigma_{13}^{(i)} + i \bar{g}_c \psi_c(r_j) \hat{a}_c \sigma_{13}^{(i)} + i \bar{g}_s \psi_s(r_j) \hat{a}_s \sigma_{13}^{(i)}$$

$$\dot{\delta}_{14}^{(i)} = -\gamma_0 - i(\Delta_p - \Delta_c + \Delta_s)\sigma_{14}^{(i)} - i \bar{g}_p \psi_p(r_j) \hat{a}_p \sigma_{14}^{(i)} + i \bar{g}_c \psi_c(r_j) \hat{a}_c \sigma_{14}^{(i)} + i \bar{g}_s \psi_s(r_j) \hat{a}_s \sigma_{14}^{(i)}$$

$$\dot{\delta}_{23}^{(i)} = -\gamma_0 - i(\Delta_s - \Delta_c)\sigma_{23}^{(i)} - i \bar{g}_p \psi_p(r_j) \hat{a}_p \sigma_{33}^{(i)} + i \bar{g}_c \psi_c(r_j) \hat{a}_c \sigma_{33}^{(i)} + i \bar{g}_s \psi_s(r_j) \hat{a}_s \sigma_{33}^{(i)}$$

$$\dot{\delta}_{24}^{(i)} = -\gamma_0 - i(\Delta_s - \Delta_c)\sigma_{24}^{(i)} - i \bar{g}_p \psi_p(r_j) \hat{a}_p \sigma_{34}^{(i)} + i \bar{g}_c \psi_c(r_j) \hat{a}_c \sigma_{34}^{(i)} + i \bar{g}_s \psi_s(r_j) \hat{a}_s \sigma_{34}^{(i)}.$$
\[ \dot{\sigma}_{34}^{(j)} = -[\gamma + \gamma_s - 2\gamma_0 - i(\Delta_s - \Delta_c)]\sigma_{34}^{(j)} - i\bar{g}_c\Psi_c(r)\sigma_{24}^{(j)} + i\bar{g}_c\Psi_s(r)\sigma_{14}^{(j)}, \]
\[ \dot{\sigma}_{11}^{(j)} = -\gamma_1\sigma_{11}^{(j)} - i\bar{g}_p\Psi_p(r)\sigma_{31}^{(j)} + i\bar{g}_c\Psi_c(r)\sigma_{13}^{(j)}, \]
\[ \dot{\sigma}_{22}^{(j)} = -\gamma_2\sigma_{22}^{(j)} + i\bar{g}_c\Psi_c(r)\sigma_{32}^{(j)} - i\bar{g}_s\Psi_s(r)\sigma_{23}^{(j)}, \]
\[ \dot{\sigma}_{33}^{(j)} = -\gamma_3\sigma_{33}^{(j)} + i\bar{g}_p\Psi_p(r)\sigma_{31}^{(j)} - i\bar{g}_s\Psi_s(r)\sigma_{32}^{(j)} - i\bar{g}_c\Psi_c(r)\sigma_{34}^{(j)}, \]
\[ \dot{\sigma}_{44}^{(j)} = -\gamma_4\sigma_{44}^{(j)} + i\bar{g}_c\Psi_c(r)\sigma_{32}^{(j)} - i\bar{g}_s\Psi_s(r)\sigma_{23}^{(j)} - i\bar{g}_p\Psi_p(r)\sigma_{31}^{(j)} + i\bar{g}_p\Psi_p(r)\sigma_{31}^{(j)} \]
\[ \dot{\rho}_p = -[\kappa - i\Delta_p]\rho_p + i\sum_j\bar{g}_p\Psi_p(r)\sigma_{13}^{(j)} + \frac{2\kappa_H}{\tau}\rho_{p0}, \]
\[ \dot{\rho}_c = -[\kappa - i\Delta_c]\rho_c + i\sum_j\bar{g}_c\Psi_c(r)\sigma_{23}^{(j)} + \frac{2\kappa_H}{\tau}\rho_{c0}, \]
\[ \dot{\rho}_s = -[\kappa - i\Delta_s]\rho_s + i\sum_j\bar{g}_s\Psi_s(r)\sigma_{34}^{(j)} + \frac{2\kappa_H}{\tau}\rho_{s0}, \]

where \( \gamma = (\gamma_1 + \gamma_2)/2 + \gamma_0, \gamma_s = \gamma_2/2 + \gamma_0, \) and \( \tau \) is the cavity round-trip time. The input fields are denoted by \( \sigma_{mn}^{(j)} \) (\( \alpha = p, c, s \)). The total cavity field decay rate (assumed equal for all fields for simplicity) is denoted by \( \kappa = \kappa_H + \kappa_T + \kappa_A \), where \( \kappa_H, L = T_H, L/2\tau \) are the decay rates corresponding to the mirrors’ transmission and \( \kappa_A = A/2 \tau \) is a decay rate corresponding to round-trip absorption losses \( A \). While these absorption losses are not essential to the understanding of the physical mechanisms studied here, we include them for completeness as they very often affect experiments with high-finesse cavities [59–61].

The previous set of equations can be solved numerically for any initial internal atomic state, input field pulses, ensemble geometry, and atomic distribution. We focus in the following on the situation in which all the atoms are in state \( |1 \rangle \) initially and the probe field is much weaker than the control and switching fields, so that one can perform a first-order expansion in the probe field to get analytical expressions for various quantities, such as the probe susceptibility, its cavity transmission and reflection, the EIT buildup time, etc.

### III. CAVITY ELECTROMAGNETICALLY INDUCED TRANSPARENCY

#### A. EIT regime

We first investigate the EIT situation where the atoms interact with both the probe and control fields, but no switching field is injected into the cavity. The input probe and control fields are abruptly switched on at time \( t = 0 \) and thereafter have constant intensities. We place ourselves in the weak probe regime, when \( \bar{g}_p|a_p| \ll g_c|a_c| \) and the intracavity photon number is much smaller than the number of interacting atoms. All the atoms are then essentially in \( |1 \rangle \), and the only nonzero atomic components at first order are the probe optical dipole \( \sigma_{13}^{(j)} \) and the ground-state coherence \( \sigma_{34}^{(j)} \) [3]. We also assume that the control field is tuned to resonance with the \( |2 \rangle \rightarrow |3 \rangle \) transition (\( \Delta_c = 0 \)) and the cavity is resonant with the \( |2 \rangle \rightarrow |3 \rangle \) transition, i.e., \( \Delta_p = \Delta_c = \delta = \Delta \). As the control field probes no atom, its intracavity amplitude reaches its steady-state value in a time \( \kappa^{-1} \). Since we are interested in getting simple analytical expressions for the steady state of the system and its dynamics over the typically slower EIT buildup times, we can consider that the control field intracavity Rabi frequency is constant and equal to its steady-state value \( \Omega_c = \bar{g}_c a_c \). Equivalently, the control field can be turned on slightly before the probe pulse is applied. The relevant equations of motion governing the evolution of the intracavity probe field are then

\[ \dot{\rho}_p = -[\kappa - i\Delta_p]\rho_p + i\sum_j\bar{g}_p\Psi_p(r)\rho_{13}^{(j)} + \frac{2\kappa_H}{\tau}\rho_{p0}, \]

\[ \dot{\rho}_c = -[\kappa - i\Delta_c]\rho_c + i\sum_j\bar{g}_c\Psi_c(r)\rho_{23}^{(j)} + \frac{2\kappa_H}{\tau}\rho_{c0}, \]

\[ \hat{\chi}(\bar{g}) = \frac{2N\bar{g}^2}{\gamma - i\Delta + \Omega^2/2}, \]

where \( \bar{g} = g_c|a_c| \) is the effective saturation parameter for the two-photon transition and \( N = \rho \Omega_c^2 L \) is the effective number of atoms defined in Refs. [68, 70]. This result can be compared to the standard situation in which the control field waist is much larger than that of the probe field [1, 3, 71].
The real and imaginary parts of these susceptibilities are plotted in Fig. 2 for typical parameters used in the experiments with ion Coulomb crystals of [61]. They show the typical transparency window in the absorption profile and the rapid change in dispersion around two-photon resonance. In comparison with the standard one, the all-cavity susceptibility clearly shows non-Lorentzian line shapes, as expected from its different dependence with respect to \( \Theta \) [Eqs. (23) and (25)].

From Eq. (20) and the input-output relations

\[
a_{p}^{\text{ref}} = \sqrt{2} \kappa \tau a_{p} - a_{p}^{\text{m}}, \quad a_{p}^{\text{tr}} = \sqrt{2} \kappa \tau a_{p},
\]

(26)

the steady-state cavity transmission and reflection for the probe field are given by

\[
T \equiv \left| \frac{a_{p}^{\text{tr}}}{a_{p}^{\text{m}}} \right|^{2} = \frac{2 \kappa_{H} \kappa_{L}}{\kappa_{H} + \kappa_{L} + \kappa_{A} - i \Delta - i \chi}^{2},
\]

(27)

\[
R \equiv \left| \frac{a_{p}^{\text{ref}}}{a_{p}^{\text{m}}} \right|^{2} = \frac{\kappa_{H} - \kappa_{L} - \kappa_{A} + i \Delta + i \chi}{\kappa_{H} + \kappa_{L} + \kappa_{A} - i \Delta - i \chi}^{2}.
\]

(28)

Using Eqs. (23) and (25) one can then compute the normal mode spectrum of the probe field transmission. In the collective strong-coupling regime, when \( g_{p} \sqrt{N} > \kappa, \gamma \), one expects three normal modes in the transmission spectrum: two modes at probe detunings \( \pm \sqrt{g_{p}^{2} N + \Omega_{c}^{2}/2} \), corresponding to the two-level ensemble modes \( \pm g_{p} \sqrt{N} \) shifted by the presence of the control field, and one mode at zero detuning for the probe (two-photon resonance here), corresponding to the cavity EIT resonance [57,71].

This is illustrated in Fig. 3, where the probe transmission spectra (normalized to the bare cavity resonant value \( 4 \kappa_{H} \kappa_{L}/\kappa^{2} \))

\[
T_{0} = \left| \frac{\kappa}{\kappa - i \Delta - i \chi} \right|^{2}
\]

(29)

is represented for the cases of (i) an empty cavity (\( \chi = 0 \)), (ii) a cavity containing a uniform density ensemble interacting with the probe field only \( [ \chi = ig_{p}^{2} N/(\gamma - i \Delta) ] \), and a cavity containing a uniform density ensemble interacting with a probe and a control field in an all-cavity (iii) and standard (iv) EIT situation, for which the probe susceptibility is given by Eqs. (23) and (25), respectively. One observes indeed that the value of the cavity transmission in the presence of EIT is restored to close to the bare cavity resonant value in a narrow frequency window around resonance. The width of the central EIT feature can be calculated by expanding the transmission around two-photon resonance. In the standard case and in the regime considered previously (\( \gamma \gamma_{0} \ll \Omega_{c}^{2} < g_{p}^{2} N \)), one finds that the probe transmission is Lorentzian shaped around \( \Delta = 0 \) (see, e.g., [3,40]).

\[
T \propto \left| \frac{1}{\kappa + \gamma_{0} \frac{g_{p}^{2} N}{\kappa_{c}^{2}} - i \Delta - \frac{\Omega_{c}^{2}}{\Delta}} \right|^{2} \propto \frac{1}{|\kappa_{\text{EIT}} - i \Delta|^{2}}.
\]

(30)

The probe field normalized transmission spectra for an empty cavity (dotted line), a cavity containing a uniform density ensemble interacting with the probe field only (dashed black line) and a cavity containing a uniform density ensemble interacting with a probe and a control field in an all-cavity (solid black line) and standard EIT situation (gray solid/dashed lines). Parameters: \( (g_{p} \sqrt{N}, \gamma, \gamma_{0}, \Omega_{c}, \kappa) = (2 \pi) \times (16, 11.2, 6 \times 10^{-4}, 6, 2.2) \) MHz. The solid and dashed grey curves show the standard EIT situation with control field Rabi frequencies \( \Omega_{c} = (2 \pi) 6 \) MHz and \( \Omega_{c} = \Omega_{c}^{\text{eff}} = (2 \pi) 6/2.2 \) MHz, respectively. Lower panel: Spectra enlarged around \( \Delta = 0 \). As discussed in the text, the latter value of the effective Rabi frequency was chosen to illustrate the lineshape difference in a situation when the all-cavity and standard EIT resonance curves have comparable halfwidths at half-maximum.
The interaction thus emulates a cavity with an effective half width
\[ \kappa_{\text{EIT}} = \gamma_0 + \kappa \frac{\Omega_s^2}{2g_p^2N}, \] (31)
which is smaller than the bare cavity half width \( \kappa \) when \( g_p\sqrt{N} \gg \Omega_s \). The analysis is a bit more complicated in the all-cavity case, due to the complex dependence of the susceptibility with the saturation parameter \( \Theta \) and the non-Lorentzian profile [as can be seen, e.g., from Fig. 3(b)].

The different dependence of the susceptibility with the effective saturation parameter \( \Theta \) makes it, in general, impossible to define an effective control field Rabi frequency in the all-cavity situation which would give the same susceptibility or transmission as in the standard case. However, if one is interested in comparing situations in which the EIT resonance features have similar widths, one can perform a similar expansion of the normalized transmission given by Eqs. (23) and (29) around \( \Delta = 0 \) and define an EIT resonance width also in the all-cavity situation. In the regime \( \Omega_s^2 \gg \gamma \gamma_0 \), the all-cavity EIT resonance width matches the standard EIT one with an effective control field Rabi frequency \( \Omega_{\text{eff}} = \Omega_s / [(\sqrt{2\pi}^2 + 4\ln(2C)^2 + \pi) / (\pi^2/2 + 2\ln(2C)^2)]^{1/2} \), where \( C = g_p^2/2\kappa\gamma \) is the cooperativity parameter for the probe field. For the parameters of Fig. 3, the scaling factor for the effective Rabi frequency is \( \sim 2.2 \), for instance. On the other hand, if one was interested in comparing minimum absorption level on two-photon resonance, one could define an effective control Rabi frequency as \( \Omega_{\text{eff}} = \Omega_s / \sqrt{\ln(2\gamma^2/\gamma \gamma_0)} \), in the EIT regime where \( \Omega_s^2 \gg \gamma \gamma_0 \) and for a given value of \( \gamma \). The resonant absorption in the all-cavity situation with a control field Rabi frequency \( \Omega_s \) could then be effectively compared to that of a standard situation in which the maximal Rabi frequency has been scaled by a factor \( \sim \sqrt{\ln(2\gamma^2/\gamma \gamma_0)} \).

Figure 4 shows the corresponding reflectivity spectra for a cavity having non-negligible round-trip absorption losses, as observed in the experiments of [61]. In general, since the reflected field results from the interference between the input field and the intracavity field, the reflectivity levels have a slightly more complex dependence on the atomic absorption and the cavity losses. The reflectivity spectrum exhibits nonetheless the same qualitative features as the transmission, with two normal modes at frequencies \( \pm \sqrt{g_p^2N + \Omega_s^2/2} \) and a third one at zero-two-photon detuning corresponding to the reduction of atomic absorption due to the EIT effect. Effective control field Rabi frequencies can also be defined in a similar fashion as previously, as shown, e.g., in Refs. [61,72].

C. Dynamics

In this section we focus on the dynamics toward reaching the steady state during a resonant EIT interaction (\( \Delta = 0 \)).

Assuming again a constant control field Rabi frequency and performing a Laplace transform of Eqs. (17)–(19) yields the following equations:
\[
(\kappa + s)a_p[s] = i \sum_j \tilde{g}_p \Psi_p(r_j) \sigma_{13}^{(j)}[s] + \sqrt{2\kappa_H/\tau} \rho_p^0[s],
\]
and calculate its time evolution by performing the inverse Laplace transform. It is, however, instructing to look at the dynamics in the adiabatic limit in which the effective cavity linewidth emulated by the EIT medium is smaller than the bare cavity linewidth and the dipole decay rate, i.e., \( \kappa_{\text{EIT}} < \kappa, \gamma \). In this limit it can be shown that the intracavity field and the optical coherence adiabatically both follow the ground-state coherence, which evolves at a rate \( \kappa_{\text{EIT}} \). In the standard case, from Eq. (33), one finds that the intracavity field amplitude increases exponentially with a time constant
1/κEIT, consistently with the steady-state spectrum analysis of the previous section. In the all-cavity case the inverse Laplace transform has to be calculated numerically. It yields a nonexponential increase in the intracavity field intensity occurring on a time scale approximately given by 1/κEIT, with Ωc scaled as in the previous section.

Figure 5 shows the time evolution of the normalized probe transmission in the two situations discussed, for the same parameters as in the previous section and for an input probe pulse abruptly switched on at t = 0 and a constant control field. For comparison the (much faster) bare cavity response is also shown.

IV. OPTICAL SWITCHING

We now turn to the all-optical switching situation, in which the transition |2⟩ ↔ |4⟩ is addressed by the switching field ˆaΔ, while the control and probe fields are in an EIT situation. When the switching field is detuned from atomic resonance (|Δ| > γc) and weak enough such that the absorption to level |4⟩ is negligible, its main effect is to light shift level |2⟩, thereby changing the bare EIT resonance condition for the control and probe fields. When the light shift becomes comparable or greater than the width of the cavity EIT window, the transmission of the probe field is inhibited, as the cavity is switched off resonance by the presence of the switching field.

A. Probe susceptibility

We assume again that almost all the atoms stay in |1⟩ and that the control and switching field intracavity Rabi frequencies have reached their steady-state values Ωc = ˆgca and Ωs = ˆgsa when the probe is injected. Performing a first-order treatment in the probe field, the equations of motion for the nonzero coherences are given by

\[ \dot{\sigma}_{14}^{ij} = -i(\gamma - i\Delta)\sigma_{14}^{ij} + i\hat{g}_p \Psi^i(r_j)\sigma_{14}^{ij} \]

\[ \dot{\sigma}_{12}^{ij} = -i(\gamma_0 - i\Delta)\sigma_{12}^{ij} + i\hat{g}_s \Psi^i(r_j)\sigma_{14}^{ij} + i\hat{g}_s \Psi^i(r_j)\sigma_{14}^{ij}. \]

Solving Eqs. (34)–(36) in steady state readily yields a mean intracavity probe field amplitude of the form (20), with a susceptibility

\[ \chi_{SW} = \frac{i\hat{g}_p^2 N}{\gamma - i\Delta \left[ \frac{\Theta \ln(1 + \Theta + \Theta_s)}{(\Theta + \Theta_s)^2} + \frac{\Theta_f}{\Theta + \Theta_s} \right]}, \]

where

\[ \Theta_s = \frac{\Omega_s^2 / 2}{(\gamma_s - i\Delta) / (\gamma_0 - i\Delta)}. \]

is defined analogously to the effective EIT saturation parameter for the probe. This susceptibility can again be compared to that of the standard case where the control and switching fields have waists much larger than that of the probe

\[ \chi_{SW} = \frac{i\hat{g}_s^2 N}{\gamma - i\Delta 1 + \Theta/(1 + \Theta_s)}. \]

B. Probe field transmission spectrum

The real and imaginary parts of both susceptibilities are shown in Fig. 6 for typical parameter values taken from [61]. As expected, in the standard case, the effect of the switching field is to shift the position of the EIT resonance by an amount that corresponds to the ac Stark shift of level |2⟩. The effect is more complex in the all-cavity case, as the shift for each atom depends on its radial position, thus leading to an asymmetric frequency behavior of the absorption and dispersion around two-photon resonance. These effects are manifest on the probe field transmission spectra, which are shown in Fig. 7 for different switching field intensities. While, in the standard configuration, the probe transmission profile is shifted away from the bare two-photon resonance without too much distortion as the switching field intensity increases, it is substantially distorted in the all-cavity case due to the different ac Stark shifts experienced by atoms at different radial positions. The accuracy of these analytical expressions for the susceptibility and transmission have been checked by numerically solving Eqs. (4)–(16). These findings are also in good agreement with the experimental observations of Ref. [61].
practical discussion on the parameters of Refs. [61,68]. We assume an asymmetric linear cavity geometry similar to that described in Ref. [61], with length \( l \approx 12 \) mm and finesse \( \sim 4000 \) and \( \kappa \approx \kappa_H = (2\pi)1.5 \) MHz. We consider an interaction with \(^{40}\text{Ca}^+\) ions on the \( 3d^3D_{3/2} \), \( m_J = +3/2 \rightarrow 4p^2P_{1/2}, m_J = +1/2 \) (probe), \( 3d^3D_{3/2}, m_J = -1/2 \rightarrow 4p^2P_{1/2}, m_J = +1/2 \) (control), and \( 3d^3D_{3/2}, m_J = -1/2 \rightarrow 4p^2P_{3/2}, m_J = +1/2 \) (switching) transitions, for which the respective maximal ion coupling strengths are \((g_p,S_{\alpha},g_{\gamma}) = (2\pi) \times (0.53,0.22,0.18) \) MHz, respectively. These coupling strengths are standardly defined by \( g_\alpha = c_\alpha \sqrt{3\pi \Gamma_\alpha / \omega_\alpha V} \) (\( \alpha = p,c,s \)), where \( c_\alpha \) and \( \Gamma_\alpha \) are the Clebsch-Gordan coefficient and partial dipole decay rate for the transition considered, \( c \) is the speed of light, and \( V = \pi w^2/2 \) is the cavity mode volume (\( w \sim 37 \) \( \mu \)m) [72]. We assume a standard situation and numerically calculate the steady-state normalized probe transmission by solving Eqs. (4)–(16) for a probe input field intensity such that the mean intracavity photon number is one in steady state in an empty resonant cavity.

Taking an effective collective coupling strength \( g_p \sqrt{N} = (2\pi)16 \) MHz renders the crystal-cavity system completely opaque for the probe field in the absence of control field (\( T_0 \approx 1\% \)). We assume fields with linewidths much smaller than the atomic and cavity linewidths and take equal cavity decay rates for all fields. We assume the atomic field Rabi frequencies as defined in Eqs. (4)–(16) to be \((\gamma_p,\gamma_c,\gamma_0) = (2\pi) \times (11.2,11.6 \times 10^{-4}) \) MHz. For the simulations the control and switching fields are injected 0.5 \( \mu \)s before the probe field, with rise times much shorter than the inverse of the cavity field decay rate, to allow them to reach their steady-state values. The mean intracavity probe photon number is then calculated in steady state, yielding the cavity transmission. Using a control field Rabi frequency \( \Omega_c = (2\pi)2 \) MHz allows for increasing the resonant probe transmission to \( \sim 90\% \). The variation of the probe transmission for different switching field detunings \( \Delta_\gamma \) and intracavity photon numbers \( n_s \) is shown in Fig. 8 under these conditions. For all these simulations we checked that the absorption of photons to level [4] was negligible and that the depletion of atoms from level [1] remained at most at the percent level. Optical switching is observed to take place with increasing photon numbers as the detuning is increased, as expected from the previous discussion and analysis. We define the minimal switching photon number \( n_s^* \) as the minimal number of intracavity switching photons needed to bring the normalized transmission from 90\% to 10\%. In the standard situation, one can easily show from Eqs. (25) and (29) that having a 90\% transmission in EIT imposes that \( n_s^* \geq 40\gamma_0 \). To get substantial switching we require that the light shift induced by the switching field \( \Omega_s^2/2\Delta_\gamma \) is a few times the width of the EIT transparency window \( \kappa_{EIT} \). A numerical estimation shows that \( \Omega_s^2/2\Delta_\gamma \sim 5\kappa_{EIT} \), which gives \( n_s^* \sim 400\gamma_0\Delta_\gamma / g_s^2 \).

In agreement with Fig. 8 we find that \(~17000\) photons are needed for the large detuning of 4.3 GHz used in Ref. [61] and \(~400\) for a detuning of \(~10\gamma_0\), the previous estimate is actually still valid for a resonant switching field replacing \( \Delta_\gamma \) by \( \gamma_\gamma \), which would give a minimal photon number of \(~40\) for the parameters of Fig. 8. This illustrative numerical example is based on the experimental parameters of [61], but we note that lower switching numbers could, in principle,
be reached, e.g., using smaller cavities or stronger switching transitions.

VI. CONCLUSION

Using a semiclassical theory for the interaction of four-level atoms with three optical cavity fields, the effect of the transverse mode profiles on the susceptibility and transmission spectrum of a probe field experiencing EIT or EIT-based optical switching has been discussed. Contrarily to the standard situation where the control and switching field Rabi frequencies are the same for all atoms, non-Lorentzian EIT can be effectively rescaled by $1/k_c$. Making the same assumptions as in Sec. III, i.e., almost all atoms in state $|1\rangle$, constant, and strong control field Rabi frequency, one gets equations of motion in an EIT situation which are similar to Eqs. (17)–(19), but now include the longitudinal dependence of the coupling with the fields

$$a_p = -(\kappa - i\Delta)a_p + ig_p \sum_j \Psi_p(r_j) (\sigma_{13,+}^{(j)} + \sigma_{13,-}^{(j)})/2$$

$$+ \sqrt{2\kappa_H/\tau a_p^{in}},$$

$$\sigma_{13,\pm}^{(j)} = -(\gamma - i\Delta)\sigma_{13,\pm}^{(j)} + ig_p \Psi_p(r_j) a_p(1 + e^{\pm 2ikz_j})/2$$

$$+ i\Omega_c \Psi_c(r_j) \sigma_{12}^{(j)}(1 + e^{\pm 2ikz_j})/2,$$

$$\sigma_{12}^{(j)} = -(\gamma_0 - i\Delta)\sigma_{12}^{(j)} + i\Omega_c \Psi_c(r_j) (\sigma_{13,+}^{(j)} + \sigma_{13,-}^{(j)})/2.$$ (A5)

If the typical time scales for the longitudinal atomic motion (trapping frequencies, thermal motion,...) are faster than the EIT dynamics time scale, but still slower as compared to the atomic dipole dynamics (i.e., if the typical longitudinal velocity $v$ is such that $\kappa EIT \ll |kv| \ll |\gamma|$, then the terms in exp($\pm 2ikz_j$) can be averaged out in Eq. (A4) and one retrieves the “delocalized” situation discussed in this paper or in the experiments of [61]. Physically, this can be explained by the fact that the moving atoms will only be in two-photon resonance with the copropagating parts of the standing waves. As the atoms hence see on average fields with a longitudinal intensity which is half the maximum of the standing-wave value, their dipole is reduced which means that the coupling strengths can be effectively rescaled by $1/\sqrt{2}$, yielding the effective Hamiltonian (2).

FIG. 8. (Color online) Probe field normalized transmission on resonance ($\Delta = 0$) as a function of intracavity switching photon number $n_s$ and for different switching field detunings $\Delta_s$: (blue) curve: $\Delta_s = (2\pi) 0$ MHz, red (middle) curve: $\Delta_s = (2\pi) 110$ MHz, green (right) curve: $\Delta_s = (2\pi) 3400$ MHz. Parameters: $(g_p/\sqrt{N}, \gamma, \gamma_c, \gamma_c)$, $\Delta_c = (2\pi) \times (16, 21, 6, 6 \times 10^{-5}, 1.5, 2.0)$ MHz.

APPENDIX: “LOCALIZED” OR “DELOCALIZED” ATOM SITUATIONS

In this Appendix we investigate the effect of the atomic motion on the cavity EIT feature. Free-space EIT with standing-wave field geometries has been investigated both theoretically [64,65,67,73–75] and experimentally [13,66], and the influence of the atomic motion on the storage and retrieval of pulses in such geometries has been discussed in, e.g., [64–67].
which are equivalent to
\[
\dot{\sigma}_p = -i(\kappa - i\Delta)\sigma_p + i\gamma_p \sum_j \Psi_p(r_j) \cos(kz_j)\sigma_1^{(j)}
\]
\[
+ \sqrt{2\kappa_H/\tau} a_p^\dagger,
\]
(A6)
\[
\sigma_1^{(j)} = -i(\gamma - i\Delta)\sigma_1^{(j)} + i\gamma_p \Psi_1(r_j) \cos(kz_j)\sigma_p
\]
\[
+ i\kappa_\epsilon \cos(kz_j)\Psi_1(r_j)\sigma_2^{(j)},
\]
(A7)
\[
\sigma_2^{(j)} = -i(\gamma - i\Delta)\sigma_2^{(j)} + i\kappa_\epsilon \Psi_1(r_j) \cos(kz_j)\sigma_1^{(j)}.
\]
(A8)
Solving Eqs. (A6)–(A8) in steady state yields a susceptibility
\[
\chi_{\text{EIT}}^{\text{cold}} = i \sum_j \frac{g_p^2 \Psi_1(r_j)^2 \cos^2(kz_j)}{\gamma - i\Delta + \frac{2\kappa_\epsilon \Psi_1(r_j)^2 \cos^2(kz_j)}{\gamma_0 - i\Delta}}.
\]
(A9)
For a large, uniform density ensemble with random longitudinal ion positions along the cavity axis, one gets
\[
\chi_{\text{EIT}}^{\text{cold}} = \frac{ig_p^2 N}{\gamma - i\Delta} \frac{2 \ln(1 + \sqrt{1 + 2\Theta})}{\Theta},
\]
(A10)
where \(\Theta\) is given by Eq. (24). The probe field transmission spectrum around two-photon resonance is shown in Fig. 9 for the same parameters as in Fig. 3(b) in the three situations considered: standard EIT and localized and delocalized all-cavity EIT. The localized situation is seen to give rise to a slightly broader EIT resonance, since the atoms see on average a slightly higher effective control field Rabi frequency, as one would intuitively expect.

If we now assume that the atoms are sufficiently cold for their longitudinal positions to be fixed with respect to the longitudinal standing-wave structure of the cavity fields during the EIT interaction, one keeps the longitudinal dependence in the coupling terms to solve the previous equations of motion.
